Received: date / Revised version: date

Abstract. The local electronic structure of $\text{YBa}_2\text{Cu}_3\text{O}_7$ has been calculated using first-principles cluster methods. Several clusters embedded in an appropriate background potential have been investigated. The electric field gradients at the copper and oxygen sites are determined and compared to previous theoretical calculations and experiments. Spin polarized calculations with different spin multiplicities have enabled a detailed study of the spin density distribution to be made and a simultaneous determination of magnetic hyperfine coupling parameters. The contributions from on-site and transferred hyperfine fields have been disentangled with the conclusion that the transferred spin densities essentially are due to nearest neighbour copper ions only with marginal influence of ions further away. This implies that the variant temperature dependencies of the planar copper and oxygen NMR spin-lattice relaxation rates are only compatible with commensurate antiferromagnetic correlations. The theoretical hyperfine parameters are compared with those derived from experimental data.

1 Introduction

Although discovered [1] in 1986, the high temperature superconducting (HTS) copper oxides continue to present challenge to both experiment and theory. The underlying mechanism (or mechanisms) responsible for their superconductivity is still ambiguous. To understand the various contributions of magnetism and phonons in high temperature superconductivity requires a detailed knowledge of the electronic structure of HTS materials. These exhibit considerable structural complexity but this complexity brings the advantage of various nuclear species located throughout the unit cell which serve as local probes of the electronic and magnetic properties. Through nuclear quadrupole and magnetic resonance (NQR and NMR) techniques, these nuclei probe passively the local electronic structure and have delivered a tremendous amount of data about both static and dynamic properties of HTS materials [2].

The nuclei experience the spin polarization of the electronic system through various hyperfine interactions which basically are well known. It turned out, however, that in HTS copper oxides their analysis is not as straightforward as expected. For example, the spin shifts which give information on the static spin susceptibility have to be separated from the chemical shifts which, being inde-

pendent on temperature, are assumed to dominate the Knight shifts at low temperature. Precise measurements of these NMR shifts in the superconducting state, however, are difficult due to the field inhomogeneities produced by the vortex lattice. Furthermore, the spin shifts at the planar copper nuclei are extremely small in all cuprates when measured with the applied field perpendicular to the planes.

Dynamic properties of the spin fluid can be probed by the various nuclear relaxation rates. The interaction energy is determined by the sum of the hyperfine interactions of which the transferred hyperfine fields make a crucial contribution as has first been pointed out in Refs. [3,4]. In particular, the variant temperature dependence of the spin-lattice relaxation rates at planar copper and oxygen nuclei could be explained by assuming that the transferred fields at ^{17}O from the two neighbouring copper ions cancel if these moments are antiferromagnetically coupled whereas the copper nuclei could reflect the antiferromagnetic spin fluctuations. Neutron scattering measurements, however, indicated that the fluctuation peaks were incommensurate and not located at the reciprocal wave vectors $Q = (\pi/a, \pi/a)$.

Zha, Barzykin, and Pines [5] then advocated transferred hyperfine fields at the oxygens from next nearest neighbour copper ions which would further suppress the contributions from the two nearest neighbours. With this

* e-mail: sam@physik.unizh.ch

extended model they could explain a variety of NMR data in good agreement with incommensurate antiferromagnetic fluctuations as exhibited by neutron scattering results.

Although the focus of NQR and NMR investigations of HTS materials has recently changed to inhomogeneities, in particular static and dynamic stripe phenomena, some of the “older” problems still wait for definitive answers. Among these problems the applicability of a one-band approach to describe the low-lying spin and charge excitations in these materials is of special importance. Several experiments [6,7,8] indicate that a second spin fluid with independent dynamics is required.

Despite the rich information these experiments provide, there exist only few theoretical first-principles approaches which address the determination of electric field gradients (EFGs) and magnetic hyperfine interactions. For the $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}$ system, EFGs at various nuclear sites have been early obtained by Das and co-workers [9,10,11] with *ab initio* cluster calculations using the unrestricted Hartree-Fock (UHF) method, and by Schwarz and co-workers [12,13] and Yu *et al.* [14], who employed the full-potential linear augmented-plane-wave method (FLAPW) within the local density approximation (LDA). Results of Hartree-Fock (HF) calculations have also been published by Winter [15]. The EFGs calculated with these three different methods agree, more or less, and reproduce apart from one exception the experimental data quite satisfactorily. The exceptional case is the EFG at the planar Cu sites. Using a large cluster that contained 74 atoms, we performed [16] calculations with the density functional (DF) method and obtained values for the Cu EFGs which were in better agreement with the experiments. These calculations were spin non-polarized and no information on magnetic hyperfine interactions was available. Spin polarized calculations, however, have recently been performed [17] for the La_2CuO_4 system which allowed the study of hyperfine coupling parameters.

In this paper, we report the results of extensive cluster studies of the electronic structure of $\text{YBa}_2\text{Cu}_3\text{O}_7$. Spin polarized calculations with the DF method with generalized gradient corrections to the correlation functionals have been performed for various clusters. The resulting electronic structure, the charge and spin distributions have been analyzed. In particular, the on-site and transferred hyperfine fields have been investigated in detail and it is demonstrated, that transferred interactions from copper ions beyond the nearest neighbours are small for both planar copper and oxygen nuclei. The relevance of this finding for the interpretation of ^{17}O NMR spin-lattice relaxation is discussed.

In Sec. 2 the clusters used in this work are described together with the basis sets and the methods of the calculations. We then consider in Sec. 3 first a $(\text{CuO}_5)^{8-}$ ion and compare the results with predictions for a Cu^{2+} ion in a single-electron approach. The results for the EFGs are given in Sec. 4 and compared to previous theoretical approaches and to experimental values. The magnetic hyperfine interactions are discussed in Sec. 5 where spe-

cial attention is given to study the transferred fields. The mechanism of spin transfer is analyzed in detail and the calculated hyperfine couplings are compared with values derived from experiments. Sec. 6 contains a summary and the conclusions.

2 Clusters and theoretical methods

The general idea of the cluster approach to electronic structure calculations of properties which depend predominantly on local structures is that the parameters that characterize a small cluster can be transferred to the solid and largely determine its behaviour. One should expect reliable results for local quantities like the EFG or the magnetic hyperfine fields. It would be much more questionable to calculate quantities which are determined only by a large region of the solid.

It would be desirable to have a cluster that contains as many atoms as possible, but there are two computational limitations to the cluster size: the available computer resources and the convergence of the minimization procedure. The rest of the solid must be simulated by a shell of neighbouring pseudopotentials and, beyond that, point charges so that the cluster experiences the correct electrostatic potential. It is necessary, however, that the results obtained should be checked with respect to their dependence on the cluster size.

An important feature of the cluster approach is that the atom to consider should be in a position of the cluster which respects as much as possible its natural surrounding. This means that the cluster should retain the “local symmetry” around that atom. Since we are interested in the EFG of both the planar copper and the chain copper, we used clusters of two different symmetries according to which copper atom we were interested in. The alternative of choosing a single cluster to look at those two ions is currently prohibitive. However both these clusters include nearest neighbour atoms of the CuO_2 planes, the latter being incorporated to reflect their proven importance.

All clusters used assume the low temperature orthorhombic structure of $\text{YBa}_2\text{Cu}_3\text{O}_7$, with lattice constants $a = 3.827 \text{ \AA}$, $b = 3.882 \text{ \AA}$ and $c = 11.682 \text{ \AA}$ as given in Ref. [18]. We adopt the standard labelling of the copper and oxygen ions as defined in Fig. 1. Using the planar $\text{Cu}(2)$ atom as a common centre, the crystallographic a -axis points towards $\text{O}(2)$, the b -axis points towards $\text{O}(3)$, and the c -axis points towards $\text{O}(4)$.

The smallest cluster used (see Fig. 1) consists of one $\text{Cu}(2)$ in the centre surrounded by four oxygen atoms ($\text{O}(2)$ and $\text{O}(3)$) of the CuO_2 plane and one $\text{O}(4)$ (which is called apical oxygen). Surrounding that central part, there are four pseudopotentials in the CuO_2 plane with a valence of +2 simulating the core electrons of $\text{Cu}(2)$ and one pseudopotential for the chain copper, $\text{Cu}(1)$, with a valence of +1, twelve pseudopotentials for the Ba^{2+} ions above the plane and twelve pseudopotentials for the Y^{3+} beneath the plane. These pseudopotentials screen the electrons of the cluster from the naked positive point charges. The cluster is labelled $\text{CuO}_5/\text{Cu}_5\text{Y}_{12}\text{Ba}_{12}$. In addition,

these 35 atoms are surrounded by more than 6500 point charges. The positions of some charges at sites far from the cluster centre were adjusted in such a way that the correct Madelung potential in the central region of the cluster was reproduced.

The largest cluster (see Fig. 2) with a $\text{Cu}(2)$ in the centre comprises in total 26 atoms all supporting a basis set; five $\text{Cu}(2)$, sixteen planar and five apical oxygens. This cluster is surrounded by a shell of eight $\text{Cu}(2)$, five $\text{Cu}(1)$, twelve Y and twelve Ba pseudopotentials. That leads to the $\text{Cu}_5\text{O}_{21}/\text{Cu}_{13}\text{Y}_{12}\text{Ba}_{12}$ cluster.

To investigate the chain copper EFG it has been necessary to construct another cluster where a $\text{Cu}(1)$ ion is in the centre. In detail the cluster contains 16 atoms, all supporting a basis set; one $\text{Cu}(1)$, two $\text{Cu}(2)$, two chain $\text{O}(1)$, two apical $\text{O}(4)$ and eight planar oxygens (four $\text{O}(2)$ and four $\text{O}(3)$). There are also four $\text{Cu}(1)$, ten $\text{Cu}(2)$, eight Ba and eight Y bare pseudopotentials. Fig. 3 shows the geometry of this cluster which is labelled $\text{Cu}_3\text{O}_{12}/\text{Cu}_{14}\text{Y}_8\text{Ba}_8$.

Table 1 contains a concise description of each cluster.

Fig. 1. The $\text{CuO}_5/\text{Cu}_5\text{Y}_{12}\text{Ba}_{12}$ cluster centred at a planar copper, $\text{Cu}(2)$. Ions with a full basis set are drawn darkly whereas ions with a pseudopotential are drawn lightly.

In view of the large range of cluster sizes used in this paper we continue our policy [17] of using the same basis set for each cluster, so that direct comparison can be made, and as before use the 6-311G basis set [19]. In any case, as earlier work has shown [17], there is no significant change if the quality of this basis set is improved. Pseudopotentials were used [20] on Ba^{2+} , Y^{3+} , and those Cu^{2+} and Cu^+ ions indicated in Figs. 1, 2, and 3. The total number of atoms, electrons, basis functions and primitive Gaussian functions for each cluster is collected in Table 2.

Fig. 2. The $\text{Cu}_5\text{O}_{21}/\text{Cu}_{13}\text{Y}_{12}\text{Ba}_{12}$ cluster centred at a $\text{Cu}(2)$.

Fig. 3. The $\text{Cu}_3\text{O}_{12}/\text{Cu}_{14}\text{Y}_8\text{Ba}_8$ cluster centred at a $\text{Cu}(1)$.

In contrast to our previous work [16] on $\text{YBa}_2\text{Cu}_3\text{O}_7$ we present here *spin polarized* calculations using the Gaussian 98 software package [19].

We showed in an earlier work [17] that the density functional (DF) method, a model which includes correlation effects, describes the covalent Cu-O bonding better than Hartree-Fock (HF) methods. Although the DF operator, equivalent to the Hamilton operator in the HF

method, is not uniquely defined, the different exchange and correlation functionals available give effectively equivalent results. In addition several forms of the gradient correction of these functionals are available. So to maintain a consistent calculational scheme, following on from our work [17] on La₂CuO₄, we persevere with the exchange functional proposed by Becke [21,22] coupled with the correlation functional of Lee, Yang, and Parr [23] (specified by the BLYP keyword in the Gaussian 98 program). For the final analysis a special program was written [24] which used the integrals and electronic wave functions from the Gaussian calculations as data.

Table 2. Compilation of the used clusters: N: number of atoms, E: number of electrons, B: number of basis functions, P: number of primitive Gaussian functions.

Cu ₃ O ₁₂ /Cu ₁₄ Y ₈ Ba ₈	15	200	273	510

To define the notation we specify that the EFG components, V^{ii} , are given here in atomic units, i.e. in $ea_B^{-3} = -|e| a_B^{-3} = -\text{Ha}/a_B^2$. The quantity $q^{ii} = V^{ii}/|e|$ then corresponds to -9.7174×10^{21} in units of V/m².

A general hyperfine interaction tensor, with components $\alpha\beta$, is denoted by $f^{\alpha\beta}$ and has units of a_B^{-3} , which importantly is independent of the underlying nuclear structure.

The hyperfine interaction energy at nucleus k is then given by

$${}^k F^{\alpha\beta} = \hbar {}^k \gamma \hbar \gamma_e f^{\alpha\beta} \quad (1)$$

where ${}^k \gamma$ and γ_e are the gyromagnetic ratios for nucleus k and the electron respectively.

We follow the NMR literature in replacing our general $f^{\alpha\beta}$ by $a^{\alpha\beta}$, for the Cu on-site term, $b^{\alpha\beta}$ and $c^{\alpha\beta}$ for the transferred hyperfine fields when it refers to Cu and O, respectively.

We can identify at least three contributions to a general $f^{\alpha\beta}$:

$$f_{\text{tot}}^{\alpha\beta} = f_{\text{iso}} \delta^{\alpha\beta} + f_{\text{dip}}^{\alpha\beta} + f_{\text{so}}^{\alpha\beta}, \quad (2)$$

where f_{iso} is the isotropic (Fermi contact) term, $f_{\text{dip}}^{\alpha\beta}$ is the traceless dipolar term, and $f_{\text{so}}^{\alpha\beta}$ the spin-orbit coupling. The difference between on-site and transferred contributions will be discussed in Sec. 5.

3 Embedded CuO₅ ion

As a starting point, we consider the (CuO₅)⁸⁻ ion (see Fig. 1) embedded in an appropriate lattice of pseudopotentials and point charges in the YBa₂Cu₃O₇ crystal. In Table 3 we collected results for the Mulliken charge ρ_M , the components of the EFG V^{ii} , the Mulliken spin density ρ , the isotropic term a_{iso} , and the diagonal elements of the dipolar hyperfine tensor a_{dip}^{ii} at the copper site. A comparison with the values in the La₂CuO₄ system [17] shows that the lacking apex oxygen in the YBa₂Cu₃O₇ compound has not a great influence on these values.

We can compare these results for the hyperfine coupling constants to the predictions of a single electron picture of a Cu²⁺ ion. Bleaney *et al.* [25] assign to a single 3d_{x²-y²} hole a dipolar coupling constant of

$$a_{\text{dip}}^{zz} = -\frac{4}{7} \langle r^{-3} \rangle \quad (3)$$

and a core polarization of

$$a_{\text{cp}} = -\kappa \langle r^{-3} \rangle. \quad (4)$$

with a parameter $\kappa = 0.26 \pm 0.06$.

In this paper we have preferred to use a_{iso} instead of a_{cp} since we are calculating the total Fermi contact interaction. This could be dominated by a_{cp} but a_{cp} is not an observable. Eq. (4) however is the correct usage for the model system proposed.

If our dipolar hyperfine coupling $a_{\text{dip}}^{zz} = -3.327 a_B^{-3}$ is inserted into Eq. (3) the estimated value for $\langle r^{-3} \rangle$ is $5.82 a_B^{-3}$ which is close to the expected value. Assuming that the isotropic hyperfine coupling is dominated by core polarization we get $a_{\text{iso}} = a_{\text{cp}} = -1.51 a_B^{-3}$ from Eq. (4) which is reasonable when compared to our properly calculated value in Table 3 of $a_{\text{iso}} = -1.97 a_B^{-3}$. We have used Eqs. (3) and (4) to get these estimates and therefore imposed the single electron picture of the Cu²⁺ ion on our cluster results. We can question what our estimate for $\langle r^{-3} \rangle$ of $5.82 a_B^{-3}$ really means since we are in a covalently bound molecular situation. In the atomic picture the larger $\langle r^{-3} \rangle$ is, the more compact is the associated atomic orbital (AO) and *vice versa*. In a molecular situation we might expect a smaller $\langle r^{-3} \rangle$ due to delocalisation of the orbital when involved in a molecular orbital (MO) but this is too simplistic for the following reason.

The operator r^{-3} will sample only the density close to the copper and so should be similar to the atomic value if the electron was not shared with other atoms. This means that the $\langle r^{-3} \rangle$ value will be proportional to the probability of finding the electron in that orbital. In theoretical

Table 3. Compilation of results for the Cu(2) in the smallest clusters: a (CuO₅)⁸⁻ ion in the YBa₂Cu₃O₇ system and a (CuO₆)¹⁰⁻ ion in the La₂CuO₄ system. The Mulliken charge and the Mulliken spin density attributed to the copper atom are denoted by ρ_M and ρ respectively. The components of the EFG, V^{ii} , are given in atomic units. The isotropic term, a_{iso} , and the dipolar hyperfine couplings, a_{dip}^{ii} , are in units of a_B^{-3} .

	ρ_M	V^{xx}	V^{yy}	V^{zz}	ρ	a_{iso}	a_{dip}^{xx}	a_{dip}^{yy}	a_{dip}^{zz}
YBa ₂ Cu ₃ O ₇	1.111	-0.582	-0.485	1.067	0.633	-1.969	1.651	1.676	-3.327
La ₂ CuO ₄	1.167	-0.706	-0.706	1.412	0.667	-1.782	1.764	1.765	-3.529

calculations this is simply the square of the MO coefficient of the copper AO. In this context Eq. (3) is probably best rewritten as

$$a_{dip}^{zz} = -\frac{4}{7}n_{atom}\langle r^{-3} \rangle_{atom} \quad (5)$$

where n_{atom} is the orbital occupancy. This equation is very useful if, and only if, $\langle r^{-3} \rangle_{atom}$ retains its value in a molecular situation. Otherwise Eq. (5) will have two unknowns but only one item of experimental data.

We have extracted $\langle r^{-3} \rangle_{atom}$ from our calculations and find that the value ($\approx 8 a_B^{-3}$) is significantly larger than the corresponding value given for the Cu²⁺ ion. This is not entirely unexpected because it has long been known that AOs are more contracted in a molecular situation if we use AOs as basis orbitals in MO theory. It was particularly noticeable for hydrogen atoms and also for d-orbitals. This effect will be amplified if bonding reduces the electron density in the AO, that is, makes the atom more positive. Although this has a passing interest it certainly raises a cautionary note here when using Eq. (3) or the modified form (5). Since no useful conclusions result from our $\langle r^{-3} \rangle = 5.8 a_B^{-3}$ derived from Eq. (3) using our theoretical value for a_{dip}^{zz} , it follows that no useful conclusion can be drawn from using any experimental value of a_{dip}^{zz} in the same way.

4 Electric field gradients

To investigate the electronic structure of the CuO₂ plane we used the cluster Cu₅O₂₁/Cu₁₃Y₁₂Ba₁₂ which comprises five Cu²⁺ ions. Calculations were performed for all three spin multiplicities $m = 2, 4$, and 6. The lowest energy is obtained for $m = 4$ probably reflecting that the spin distribution is reminiscent of an antiferromagnetic system. The corresponding energy differences $E_{m=6} - E_{m=4}$ and $E_{m=2} - E_{m=4}$ are plotted in Fig. 4 versus the product $\rho_0(\rho_1 + \rho_2 + \rho_3 + \rho_4)$ where ρ_0 denotes the Mulliken spin density of the central copper ion and ρ_i ($i = 1, \dots, 4$) that at the four other copper ions. It is seen that the calculated energies are related to the product of the Mulliken spin densities according to

$$E_m - E_{m=4} = j\rho_0(\rho_1 + \rho_2 + \rho_3 + \rho_4) \quad (6)$$

with $j = 283$ meV. This empirical relationship and its connection with the antiferromagnetic exchange interaction will be further discussed elsewhere together with a comparison of the analogous results for other materials.

Fig. 4. Dependence of the calculated energy differences $E_{m=6} - E_{m=4}$ and $E_{m=2} - E_{m=4}$ on the Mulliken spin densities.

In Table 4 the calculated values of the EFG components at the central copper atom are reported. The experimental values for the quadrupole resonance frequencies [26] have been converted into EFGs using the value of $Q(^{63}\text{Cu}) = -0.211$ b for the nuclear quadrupole moment [27]. Also given in Table 4 are previous theoretical values obtained from band structure calculations [12,14] and from a spin non-polarized cluster calculation [16]. The present results are in good agreement with the experimental data. Our values slightly depend on the spin multiplicity which reflects the influence of the finite size of the cluster since for $m = 4$ the absolute value of the (negative) Mulliken spin density at the central copper ion is smaller than that at the four other copper atoms. This will be further discussed in the next section. A comparison of the EFG values obtained in the small cluster CuO₅/Cu₅Y₁₂Ba₁₂ (see Table 4) and the values at the four non-central copper ions in the large cluster ($V^{zz} = 1.41$) shows good convergence with respect to cluster size. It should be emphasized, however, that the experimentally determined value for the asymmetry parameter ($\eta = 0.01$) cannot be accounted for by theoretical calculations which are based on atomic sites determined by crystallographic data. Although the orthorhombicity is small ($(b-a)/b = 0.014$) an asymmetry is expected which is appreciably larger than that observed experimentally.

It is noted here that the EFG at the copper nucleus results from relatively large and almost cancelling individual contributions, as is illustrated in Table 5 for the example of Cu with spin multiplicity $m = 4$. This demonstrates that the theoretical determination of EFGs is quite delicate, as a further detailed analysis [28] will show. There-

fore, it is necessary to describe the total electron density of the atom as accurately as possible, which require the basis sets to be sufficiently large. (In our experience, the 6-311G basis sets [19] have proved adequate as has been shown for La₂CuO₄ where the dependence of the EFG at Cu on the basis set was discussed in detail [17].)

A comparison of the theoretical results with experimental values shows that the new spin-polarized calculations here are distinctly better than our previous spin-unpolarized calculations [16] and the FLAPW calculations [12,14]. The FLAPW values are only about 50% of the experimental values although the contributions from the 3p and 3d orbitals (with the exception of the 3d_{x²-y²} orbital) are almost identical with our current calculations. The exception is crucial since according to our calculations the 3d_{x²-y²} orbital is significantly involved in covalent bonding with the 2p_σ orbitals on the nearest neighbour planar oxygen atoms. The bonding to the apical oxygens is much more ionic. Clusters are basically molecular ions surrounded by an environment of atomic ions represented by pseudopotential functions or, more remotely, point charges. The wave functions are determined by a molecular orbital approach which is ideally suited to the study of systems which are significantly covalently bonded. Augmented plane wave methods are more suited to systems which are mainly held together by ionic or metallic bonds. For this reason we believe that the cluster calculations are more appropriate than the FLAPW method for the study of local properties in these crystals.

The values of the EFG components at the planar oxygen sites O(2) and O(3) are collected in Table 6 together with previous theoretical values and experimental data for resonance frequencies which have been converted into EFGs using the value $Q(^{17}\text{O}) = -0.02556$ b. The agreement between theory and experiment is good.

The cluster Cu₃O₁₂/Cu₁₄Y₈Ba₈ was used to investigate the electronic structure of the apical oxygen O(4) and the chain copper Cu(1) with spin multiplicities $m = 3$ and $m = 5$. The experimentally determined EFG components at Cu(1) exhibit the peculiar feature that the asymmetry parameter η is almost equal to 1 which is not due to a particular symmetry of the lattice site. Our cluster calculations with $m = 5$ fail badly to reproduce this asymmetry but those with $m = 3$ give $\eta = 0.995$ as shown in Table 7. For the latter, the spin densities reside mainly in the two planes with small values on the Cu(1) and the O(4). Nevertheless, the interplanar exchange coupling is of general interest. A careful study of this problem would, however, require much larger clusters (at least 11 copper ions) which are part of our plans for future investigations.

For the apical oxygen, O(4), we obtain $V^{zz} = -1.61$ and $\eta = 0.22$ also in reasonable agreement with experiments [29] ($|V^{zz}| = 1.22$ and $\eta = 0.32$) in consideration of the small, but carefully chosen, cluster.

5 Magnetic hyperfine couplings

5.1 Isotropic contributions

In the previous section, we have shown that our wave functions can reasonably well predict the EFGs at various sites. Therefore we feel sufficiently confident to calculate other quantities from these wave functions, focusing in this section particularly on the magnetic hyperfine interactions in the CuO₂ plane.

The magnetic hyperfine interaction tensor at a certain nucleus can be decomposed into an isotropic part D and a traceless dipolar part T , the latter being discussed in the next subsection. The former is given by the difference between the spin-up and spin-down density at the nuclear site R

$$D(\mathbf{R}) = \frac{8\pi}{3} \left(\sum_m |\psi_m^{\uparrow}(\mathbf{R})|^2 - \sum_{m'} |\psi_{m'}^{\downarrow}(\mathbf{R})|^2 \right) \quad (7)$$

where the sums extend over all occupied MOs.

In a restricted open-shell calculation, the sum $\sum_{m'} |\psi_{m'}^{\downarrow}(\mathbf{R})|^2$ would exactly cancel the partial sum $\sum_{m'} |\psi_{m'}^{\uparrow}(\mathbf{R})|^2$ counting over the number of spin-down MOs only and $D(R)$ would be determined solely by the remaining (open-shell) MOs with spin up. In this case, $D(R)$ corresponds to the Fermi contact term which is produced by AOs that are spherically symmetric around R . For unrestricted open-shell calculations, as they are discussed here, all MOs with spin up differ from those with down spin. If there are no singly occupied MOs with dominantly s-like AO contribution, as for example in the (CuO₅)⁸⁻ ion discussed above, the quantity $D(R)$ is interpreted as core polarization. In the present context, we have both kinds of contributions. In a first approximation, the MOs with mostly 3d_{x²-y²}-character are singly occupied and yield a core polarization contribution to $D(\text{Cu})$. Neighbouring copper ions produce in addition transferred hyperfine fields which produce a Fermi contact interaction from the 4s-orbitals and a much smaller contribution from the inner 3s-, 2s-, and 1s-orbitals by spin polarization, in other words, a core polarization. We therefore prefer to

call $D(R)$ just the isotropic hyperfine density at the nuclear site R .

The cluster calculations allow us to scrutinize the on-site and transferred hyperfine field in detail. We first focus on the analysis of $D(\text{Cu})$ using results from calculations with the highest possible spin multiplicity. Thus in the cluster Cu₅O₂₁/Cu₁₃Y₁₂Ba₁₂ with $m = 6$ we have $D(\text{Cu}) = 0.13 \text{ a}_B^{-3}$ at the central copper nucleus, but $D(\text{Cu}) = -1.33 \text{ a}_B^{-3}$ at the four other copper nuclei. For the small cluster CuO₅/Cu₅Y₁₂Ba₁₂, we got $D(\text{Cu}) = -1.97 \text{ a}_B^{-3}$. Furthermore, we have replaced copper ions in the cluster Cu₅O₂₁/Cu₁₃Y₁₂Ba₁₂ by pseudopotentials without basis sets. This allows us to determine $D(\text{Cu})$ when there are two nearest neighbour (NN) copper ions. The values for $D(\text{Cu})$ obtained in this way are plotted in Fig. 5 as a function of the number of NN.

It is seen, that the isotropic hyperfine density is proportional to the number of NN. In the same way it is found that $D(\text{O})$ at the planar oxygen site is about 0.6 a_B^{-3} when there is one NN and about 1.2 a_B^{-3} for oxygens be-

tween two copper ions. The sensitivity of the calculated spin densities can be assessed by an inspection of the two values obtained for $D(\text{Cu})$ with NN = 1 or NN = 2 in Fig. 5. The slightly different values are due to the small orthorhombicity: the hyperfine density at the central copper nucleus in a cluster with three coppers aligned along the crystallographic direction a amounts to -0.99 a_B^{-3} but to -1.06 a_B^{-3} for direction b .

In the same way we can analyze the results of calculations with lower spin multiplicities. A careful analysis of all results shows that the isotropic hyperfine coupling can well be explained by the following ansatz:

$$D(\text{Cu}_i) = \alpha_{iso} \rho(\text{Cu}_i) + \beta_{iso} \sum_{j \in \text{NN}} \rho(\text{Cu}_j). \quad (8)$$

Plotting $D(\text{Cu}_i)/\rho(\text{Cu}_i)$ against $\sum_{j \in \text{NN}} \rho(\text{Cu}_j)/\rho(\text{Cu}_i)$ should then result in a straight line with slope β_{iso} and intersection α_{iso} . This is done in Fig. 6.

Fig. 5. Isotropic hyperfine density (in units of a_B^{-3}) at the central copper nucleus plotted against number of nearest copper neighbours.

Fig. 6. $D(\text{Cu}_i)/\rho(\text{Cu}_i)$ plotted against $\sum_{j \in \text{NN}} \rho(\text{Cu}_j) / \rho(\text{Cu}_i)$. The different markers correspond to symmetrically inequivalent copper sites in the cluster which differ by their number of nearest neighbours.

Similarly the isotropic hyperfine density at an oxygen site can be written as

$$D(\text{O}) = \gamma_{iso} \sum_{j \in \text{NN}} \rho(\text{Cu}_j). \quad (9)$$

Figure 7 displays the obtained values in a plot similar to the copper case. Again, the quality of the ansatz can be estimated by noting that the data points fit quite well to a straight line with slope γ_{iso} . From these two figures it seems quite clear that the influence of further distant atoms can be considered small. To make things more quantitative we have assumed the isotropic hyperfine density at copper and oxygen to depend as well on next nearest

Fig. 7. Isotropic hyperfine density at the planar oxygen nuclei (in units of a_B^{-3}) plotted against $\sum_{j \in \text{NN}} \rho(\text{Cu}_j)$. The three different markers indicate different spin multiplicities: $\circ$ denotes $m = 6$, $\square$ denotes $m = 4$, and $\triangle$ denotes $m = 2$.

neighbours (NNN) and further distant copper ions according to

$$D(\text{Cu}_i) = \alpha_{iso} \rho(\text{Cu}_i) + \beta_{iso} \sum_{j \in \text{NN}} \rho(\text{Cu}_j) + \beta'_{iso} \sum_{j \in \text{NNN}} \rho(\text{Cu}_j) \quad (10)$$

at a copper nucleus and

$$D(\text{O}) = \gamma_{iso} \sum_{j \in \text{NN}} \rho(\text{Cu}_j) + \gamma'_{iso} \sum_{j \in \text{NNN}} \rho(\text{Cu}_j) + \gamma''_{iso} \sum_{j \in \text{NNNN}} \rho(\text{Cu}_j) \quad (11)$$

at an oxygen nucleus. A least squares fit to all data yields $\alpha_{iso} = -2.68 \pm 0.02$, $\beta_{iso} = 0.72 \pm 0.01$, and $\beta'_{iso} = -0.03 \pm 0.02$ for the constants concerning the copper nucleus and $\gamma_{iso} = 0.95 \pm 0.01$, $|\gamma'_{iso}| < 0.025$, and $|\gamma''_{iso}| < 0.03$ for those concerning the oxygen nucleus (in units of a_B^{-3}).

It should be noted, that the marginal contribution of NNN ions to $D(\text{O})$ is of particular relevance for the interpretation of the ^{17}O NMR relaxation rates. To demonstrate this small contribution we plot in Fig. 8 the values of $D(\text{O})$ as a function of NNN copper ions. The implications of this result will be discussed further in Sec. 6.

5.2 Dipolar hyperfine coupling

The dipolar hyperfine coupling results from a spatial average of $1/r^3$ with wave functions:

$$T^{\alpha\beta}(\mathbf{R}) = \sum_m \langle \psi_m^\dagger(\mathbf{r}) | \Delta^{\alpha\beta}(\mathbf{r} - \mathbf{R}) | \psi_m^\dagger(\mathbf{r}) \rangle -$$

Fig. 8. Isotropic hyperfine density (in units of a_B^{-3}) at the planar oxygen nuclei as a function of the number of next nearest neighbour copper ions.

$$-\sum_{m'} \langle \psi_{m'}^\downarrow(\mathbf{r}) | \Delta^{\alpha\beta}(\mathbf{r} - \mathbf{R}) | \psi_{m'}^\downarrow(\mathbf{r}) \rangle \quad (12)$$

with

$$\Delta^{\alpha\beta}(\mathbf{r}) = \frac{3x^\alpha x^\beta - \delta^{\alpha\beta} |\mathbf{r}|^2}{|\mathbf{r}|^5}. \quad (13)$$

At variance with the isotropic hyperfine density which for copper exhibits a substantial transferred contribution, $T^{ii}(\text{Cu})$ is dominated by the on-site term. The transferred field from NN copper ions is small as can be seen in Fig. 9 where $T^{zz}(\text{Cu})$ is plotted as a function of the number of NN.

Fig. 9. The dipolar hyperfine field at the planar Cu(2) nucleus $T^{zz}(\text{Cu})$ (in units of a_B^{-3}) as a function of the number of nearest neighbour copper ions. Note that there is no substantial dependence of $T^{zz}(\text{Cu})$ on NN.

Again, all obtained values for the different clusters and multiplicities turned out to be proportional to the copper Mulliken spin densities and the same kinds of ansatz that worked for the isotropic case could be used. The results of this analysis can be written as

$$T^{zz}(\text{Cu}_i) = \alpha_{dip}^\parallel \rho(\text{Cu}_i) + \beta_{dip}^\parallel \sum_{j \in NN} \rho(\text{Cu}_j) \quad (14)$$

and

$$T^{ii}(\text{O}) = \gamma_{dip}^{ii} \sum_{j \in NN} \rho(\text{Cu}_j). \quad (15)$$

The fitted parameters $\alpha_{dip}^\parallel$, $\beta_{dip}^\parallel$, and γ_{dip}^{ii} are collected in Table 8.

5.3 Discussion of spin density distribution

The capability of the cluster approach to control the spin multiplicities enables us to get insight into the details of on-site and transferred spin densities. In Fig. 10 the difference of spin-up and spin-down densities is shown along a bond axis for multiplicities $m = 6$ (upper panel) and $m = 4$ (lower panel) calculated with the Cu₅O₂₁/Cu₁₃Y₁₂Ba₁₂ cluster. The double humps at the coppers reflect the fact that the dominant part of the spin density distribution is related to the projections of the MOs onto the 3d_{x²-y²} AOs. The small differences in the heights are due to the finite size of the cluster. The contact density at the two outer coppers is negative (they have only one NN) but positive at the central copper (with four NN). At the oxygens, the spin density resides mainly on the 2p_σ AO. Again, the tiny peaks at the positions of the nuclei reveal the contact densities which for the two inner oxygen atoms with two NN is twice as large as for the two outer oxygens with only one NN. The “antiferromagnetic” alignment ($m = 4$, lower panel of Fig. 10) also exhibits finite size effects. Since there are four copper ions with spin up and only one with spin down, there is an excess of positive spin density in the cluster which prohibits an exact cancellation of $\rho^\uparrow$ and $\rho^\downarrow$ at the bridging oxygens. The smaller spin density distribution on the central copper atom in the antiferromagnetic case may arise from the removal of the restrictions due to the exclusion principle for the central spin compared to the $m = 6$ case. Note, however, that the electronic structure and spin density distributions for all the clusters are in perfect accordance if the analysis is performed with the individual Mulliken spin densities $\rho(\text{Cu})$ as has been demonstrated in the previous subsection (see Figs. 6 and 7).

An extrapolation from the finite clusters to an extended system therefore just requires the knowledge of $\rho(\text{Cu})$. We assume that the value calculated for the central copper atom in the large cluster, $\rho(\text{Cu}) = 0.68$, is a reasonable estimate. The resulting hyperfine coupling constants ($a_{iso} = 0.68\alpha_{iso}$ and, similarly, for the other couplings) will be given and discussed in the next subsection.

Table 8. The values of the fitted parameters of our ansatz (14) for the dipolar hyperfine field at Cu(2) and (15) for that at O(2/3) (in units of a_B^{-3}). Note that the dipolar field at the copper nucleus is nearly axially symmetric and $\alpha_{dip}^{\parallel}$ refers to the crystallographic c -direction. For the planar oxygens, $\gamma_{dip}^{\parallel}$ ($\gamma_{dip}^{\perp}$) denotes the component in the CuO₂ plane along (perpendicular to) the bond axis.

$\alpha_{dip}^{\parallel}$	$\beta_{dip}^{\parallel}$	$\gamma_{dip}^{\parallel}$	$\gamma_{dip}^{\perp}$	γ_{dip}^c
-5.16 ± 0.01	0.136 ± 0.004	0.47 ± 0.01	-0.26 ± 0.01	-0.21 ± 0.01

Fig. 10. Spin density distribution (in a_B^{-3}) along the crystallographic axis a in the cluster Cu₅O₂₁/Cu₁₃Y₁₂Ba₁₂. The upper (lower) panel displays the results from a calculation with spin multiplicity $m=6$ ($m=4$).

To illustrate the mechanisms of spin transfer, the radial dependence of the difference between spin-up and spin-down densities at the oxygen and the copper is shown in Figs. 11 and 12 for the clusters CuO₅/Cu₅Y₁₂Ba₁₂ and Cu₅O₂₁/Cu₁₃Y₁₂Ba₁₂. Owing to overlap and covalence effects the Cu²⁺ ion shares its spin density with the ligand planar oxygens whose spin direction is parallel to that of the local copper moment. The transferred spin is mainly on the O 2p_σ orbital with a polarization of 8.2% and polarizes the s-orbitals such that the nucleus sees positive spin density. This can be seen in Fig. 11 (left panel) where the radial dependence of D near the oxygen nucleus is shown separately for the projections onto the 1s and 2s AOs. The contact densities are $D_{2s}(O) = 0.737 a_B^{-3}$ and $D_{1s}(O) = -0.154 a_B^{-3}$. If the oxygen is between two NN copper ions (right panel) the contact densities are approximately doubled to $D_{2s}(O) = 1.543 a_B^{-3}$ and $D_{1s}(O) = -0.304 a_B^{-3}$. The densities $|\psi_{ns}^{\uparrow}(O)|^2$ and $|\psi_{ns}^{\downarrow}(O)|^2$ are almost identical with values $|\psi_{1s}(O)|^2 = 141 a_B^{-3}$ and $|\psi_{2s}(O)|^2 = 6.79 a_B^{-3}$. Defining the polarizations f_{ns} of the s-like orbitals by

$$D_{ns}(O) = \frac{8\pi}{3} |\psi_{ns}(O)|^2 f_{ns} \quad (16)$$

we get $f_{2s} = 1.3\%$ and $f_{1s} = -0.013\%$ with NN = 1 but $f_{2s} = 2.7\%$ and $f_{1s} = -0.026\%$ for NN = 2.

Fig. 11. Radial dependence (along bond direction in units of a_B) of D (in a_B^{-3}) subdivided into contributions from MOs with mainly 1s and 2s AO character at a planar oxygen nucleus for the small cluster CuO₅/Cu₅Y₁₂Ba₁₂ with NN = 1 (left panel) and for the large cluster Cu₅O₂₁/Cu₁₃Y₁₂Ba₁₂ with NN = 2 (right panel).

The isotropic spin density distributions near the Cu nucleus are shown in Fig. 12, for NN = 0 (NN = 4) in the left (right) panel. The corresponding numerical values are summarized in Table 9. The hyperfine fields transferred from the four NN ions change the polarization of the 4s-orbital from negative to positive.

5.4 Hyperfine Couplings

The results for the magnetic hyperfine couplings for the planar oxygen are represented in Table 10. The spin-orbit contributions to the hyperfine couplings are expected to be small in the case of oxygen. We neglect them and assume that $c_{tot}^{ii} = c_{iso} + c_{dip}^{ii}$. The values are very similar to the ones calculated for La₂CuO₄ (see Ref. [17]) with the exception that now c_{tot}^c is somewhat larger than $c_{tot}^{\perp}$.

Experimentally, these couplings cannot be measured directly but they are derived from a combination of various data. The spin shift measured with the external field in direction i is proportional to c_{tot}^{ii} and the static uniform spin susceptibility. The spin-lattice relaxation rates are proportional to the sum of the squares of c_{tot}^{jj} in the directions orthogonal to i . Whereas the overall agreement between the theoretical and experimental values is satisfying, it should

Table 9. Values of the s-like AOs at the Cu (in a_B^{-3}), the isotropic hyperfine densities (in a_B^{-3}), and polarizations f_{ns} for the cluster CuO₅/Cu₅Y₁₂Ba₁₂ (NN = 0) and the cluster Cu₅O₂₁/Cu₁₃Y₁₂Ba₁₂ (NN = 4).

**Fig. 12.** Radial dependence (along bond direction in units of a_B^{-3}) of D (in a_B^{-3}) subdivided into contributions from MOs with mainly 1s, 2s, 3s, and 4s AO character at a planar copper nucleus for the small cluster CuO₅/Cu₅Y₁₂Ba₁₂ with NN = 0 (left panel) and for the large cluster Cu₅O₂₁/Cu₁₃Y₁₂Ba₁₂ with NN = 4 (right panel).

be noted that the calculated anisotropy, $c_{tot}^{\parallel}/c_{tot}^{\perp} \simeq 2$, is larger than the experimental value of about 1.7.

When comparing the theoretical values with those derived from experiments (see Table 10) it is seen that the latter values are generally higher. The experimental analysis relies on the approximation that the total spin susceptibility χ_s is isotropic and on the uncertain assumption that it is equally distributed over Cu(2) and Cu(1) sites. (In Ref. [30] the value $\chi_s = 27.5 \times 10^{-5}$ emu/mole divided by 2.96 appropriate for the YBa₂Cu₃O_{6.96} sample was used.) Johnston and Cho [31] reported anisotropic spin susceptibilities $\chi_s^{\parallel}$ ($\chi_s^{\perp}$) of 37.4 (33.5) $\times 10^{-5}$ emu/mole. Using these values and the spin shifts from Ref. [30] the

hyperfine coupling constants would be $c_{tot}^{\parallel} = 0.98 a_B^{-3}$, $c_{tot}^{\perp} = 0.58 a_B^{-3}$, and $c_{tot}^c = 0.61 a_B^{-3}$.

Yoshinari *et al.* [30] also found that the hyperfine fields did not appreciably change between samples with an oxygen content of $x = 6.6$, 6.8 , and 6.96 . This is in sharp contrast with recent measurements [32] in the La₂CuO₄ system where large differences between the hyperfine fields in undoped and doped (0.15% Sr) compounds have been observed.

The calculated values for the isotropic and dipolar hyperfine couplings for the planar copper are given in the left part of Table 11. We cannot yet calculate from first principles the spin-orbit contribution which for copper is not negligible. The total values for the on-site densities, $a_{tot}^{ii} = a_{iso} + a_{dip}^{ii} + a_{so}^{ii}$, however, depend crucially on a_{so}^{ii} , partly accidentally as will be shown below. We therefore choose to adopt the estimates given in Ref. [33] which are based on the picture of a single missing electron in the copper 3d-shell developed by Bleaney *et al.* [25]. From perturbation theory the hyperfine spin-orbit coupling densities are given by a phenomenological spin-orbit coupling parameter λ , the energy differences ΔE between the various 3d-orbitals and $\langle r^{-3} \rangle$. Using the “standard” values for these quantities which are obtained from a variety of combined experimental and theoretical studies, one obtains $a_{so}^{\parallel} = 2.409 a_B^{-3}$ and $a_{so}^{\perp} = 0.427 a_B^{-3}$. Following the arguments given by Monien, Pines, and Slichter [33] who estimate the uncertainties in λ and ΔE to about 20% and adding 10% for the possible change in $\langle r^{-3} \rangle$, we include the 30% bounds in the “errors” given for $a_{tot}^{\parallel}$ and $a_{tot}^{\perp}$ in Table 11.

In comparing our calculated values with previous estimates and values derived from experiment, we first note that we also get a transferred anisotropic hyperfine coupling $b_{dip}^{\parallel}$ which is 18% of the value of b_{iso} . The value for b_{iso} of $0.49 a_B^{-3}$ is considerably smaller than that of $0.71 a_B^{-3}$ obtained in the La₂CuO₄ compound [17]. This is due to the buckling of the planar oxygens in the CuO₂ plane [36]. Experiments give constraints on various com-

Table 11. The hyperfine couplings for the planar copper atom and comparison with literature values (in units of a_B^{-3}). The errors assigned to the total on-site hyperfine couplings originate from the uncertainties of the spin-orbit couplings as discussed in the text. (Since the dipolar hyperfine interaction tensor is traceless and nearly axially symmetric, $a_{dip}^\perp \simeq -\frac{1}{2}a_{dip}^\parallel$ and $b_{dip}^\perp \simeq -\frac{1}{2}b_{dip}^\parallel$).

	a_{iso}	b_{iso}	$a_{dip}^\parallel$	$b_{dip}^\parallel$	$a_{so}^\parallel$	$a_{so}^\perp$	$a_{tot}^\parallel$	$a_{tot}^\perp$
this work	-1.82	0.49	-3.51	0.09	2.41	0.43	-2.93 ± 0.72	0.36 ± 0.18

binations of the coupling parameters. Measurements of the ⁶³Cu NMR frequencies in the insulating antiferromagnetic compounds YBa₂Cu₃O₆ and La₂CuO₄ give similar frequencies of about 90 MHz. This then determines $|a_{tot}^\perp - 4(b_{iso} + b_{dip}^\perp)| = 1.92 \text{ a}_B^{-3}$ if an effective localized magnetic moment of $0.66 \mu_B$ is assumed. Our values from Table 11 yield 1.42 a_B^{-3} . A second constraint comes from the anisotropy ratio R of the nuclear spin-lattice relaxation rates for fields perpendicular and parallel to the planes which is found to be about 3.7. Assuming antiferromagnetically correlated spins R is given by

$$R = \frac{1}{2} \left[1 + \left(\frac{a_{tot}^\parallel - 4(b_{iso} + b_{dip}^\parallel)}{a_{tot}^\perp - 4(b_{iso} + b_{dip}^\perp)} \right)^2 \right]. \quad (17)$$

Inserting our calculated hyperfine couplings into Eq. (17) yields values for R which are far too large. An inspection of Eq. (17), however, shows that R depends sensitively on $a_{tot}^\perp$. In the nominator both terms add since $a_{tot}^\parallel < 0$. In the denominator, however, a cancellation takes place since $a_{tot}^\perp > 0$, and the relative values of the terms are important. Due to the accidental near cancellation of a_{iso} and $a_{dip}^\perp$ ($a_{iso} + a_{dip}^\perp = -0.068 \text{ a}_B^{-3}$), the value of $a_{so}^\perp$ is crucial for $a_{tot}^\perp$, as has been shown by Stoll *et al.* [37] for La₂CuO₄ where, in addition, the spin-orbit contributions to the hyperfine field at the copper nucleus are strongly influenced by Sr²⁺ dopants. Therefore the calculated couplings are inadequate in predicting the anisotropy of the Cu relaxation rates until more reliable values for $a_{so}^\perp$ are available.

A third experimental constraint comes from the fact that the copper magnetic shift measured for fields perpendicular to the plane is independent of temperature and therefore assigned entirely to contributions from the chemical shift leaving a vanishing spin shift $^{63}K_s^\parallel$. This can happen if $a_{tot}^\parallel + 4(b_{iso} + b_{dip}^\parallel) = 0$. Our calculated values in Table 11 give -0.61 a_B^{-3} and a value of $a_{so}^\parallel \simeq 3 \text{ a}_B^{-3}$ would be required for a perfect cancellation. It should be emphasized, however, that $^{63}K_s^\parallel$ is found to be strictly temperature independent for most of the cuprates irrespective of the doping level. This is a remarkable experimental fact and an accidental cancellation of the various terms for sev-

eral substances and doping levels is completely unexpected from our theoretical calculations of hyperfine parameters.

6 Summary and Conclusions

The local electronic structure of YBa₂Cu₃O₇ has been investigated by first-principles methods. Using clusters of various sizes, which attempt to incorporate the important features of the CuO₂-plane, the EFGs at the planar copper and oxygen sites were calculated with all-electron calculations and sufficiently large basis sets. The calculated values are in good agreement with the experiments. An inspection of Table 5, where we examined in detail the various contributions to the EFG at the copper nucleus, demonstrates that the traditional interpretation of EFG values using Sternheimer shielding and antishielding factors is highly questionable.

The magnetic hyperfine properties in the planes have been determined very accurately by comparing the results from calculations with different spin multiplicities. It was shown that the transferred hyperfine fields at both Cu(2) and O(2/3) are effectively due only to the nearest neighbour copper ions, the contributions from further distant neighbours being marginal. This finding has important consequences since it shows that the assumption of Zha, Barzykin, and Pines [5] has no microscopic justification. The variant temperature dependencies of the Cu(2) and O(2/3) nuclear spin lattice relaxation rates can then only be explained by antiferromagnetic fluctuations which are commensurate. It can be argued that the neutron scattering which exhibits incommensurate fluctuations is operating on a much faster time scale than the NMR experiments or is probing periodic arrays of domain walls.

The calculated values for the hyperfine coupling constants are in reasonable agreement with the values expected from experimental data. As the discussion in Sec. 5 demonstrated, the interpretation of the data is made difficult by the uncertainty of the contributions of the spin-orbit interaction. In this respect, improved quantum chemical calculations of the spin-orbit coupling would be desirable.

The initial studies for this work were done in the diploma work of W.O. Dijkstra whose careful analysis is

gratefully acknowledged. We express our gratitude to J. Haase, M. Mali, J. Roos, H.U. Suter, and R.E. Walstedt for enlightening discussions. This work is partially supported by the Swiss National Science Foundation.
